Project Goals: The Great Lakes Bioenergy Research Center supports research that generates technology for the conversion of cellulosic biomass to biofuels. However, agricultural production of cellulosic biomass is associated with emissions of greenhouse gases such as N₂O and CO₂. N₂O is particularly problematic because it has a 100-year global warming potential 300 times that of CO₂ and is the leading cause of stratospheric ozone depletion. Currently the relative importance of microbial processes contributing to N₂O flux is poorly understood. Stable isotopes of N and O have emerged as a tool to discriminate between pathways responsible for N₂O flux. The goals of our project are to (1) determine the sources of microbial N₂O production in soil communities using stable isotopes, (2) elucidate the biochemical pathways of N₂O production associated with specific naturally occurring enzymes and (3) develop methodology for real-time source determination via stable isotope analysis using laser spectroscopy.

Site preference (SP), the difference in the isotope ratios between the central and terminal N atoms in nitrous oxide (N₂O), has emerged as a robust discriminator of the microbial origins of N₂O. SP has emerged as a conservative tracer of N₂O production, differentiating N₂O produced bacterial nitrification and denitrification. In contrast, the δ¹⁵N and δ¹⁸O of N₂O are not conservative tracers of N₂O production. A number of variables (e.g. electron donor abundance, nitrogen substrate and growth rate) markedly influence the δ¹⁵N and δ¹⁸O of N₂O. Importantly, the influence of these variates on SP has not been documented. Thus, we investigated the influence of these variates on SP with different bacterial denitrifiers. Specifically, we examined the effect of the electron donor source (citrate or succinate) and concentration (10, 1, 0.1, and 0.01 mM) on SP in Pseudomonas chlororaphis subsp. chlororaphis and Pseudomonas chlororaphis subsp. aureofaciens. There was no net isotope effect (no shift in SP) observed across the conditions evaluated (ANOVA, p>0.05). These data confirm that SP is a conservative tracer of N₂O production. The observation that SP differed slightly between our two denitrifiers suggests that changes in the predominance of different bacterial species may account for some of the variation in SP for denitrifiers reported in the literature.

In addition to evaluating the influence of different factors on SP, we are now beginning to evaluate how differences in enzymatic mechanisms contribute to variation in SP. We are specifically interested in nitric oxide reductases (NORs), which are responsible for converting nitric oxide (NO) to N₂O. We have chosen to examine if shifts in SP occur for bacterial
cytochrome c-dependent NOR, bacterial quinol-dependent NOR, and hydroxylamine oxidoreductase.

Trace gas-isotope ratio mass spectrometry (TG-IRMS) is the current gold standard for isotopic measurements of N₂O; however, the sporadic nature of N₂O production, along with the costs and analytical time associated with TG-IRMS create challenges to its large scale application. Isotopic analysis of N₂O via laser spectroscopy offers both reduced analytical time, in situ analysis, and continuous real-time measurements of SP. We show that SP determinations from the LGR are comparable to those generated by traditional TG-IRMS. Further, we are able to measure SP at atmospheric concentrations without pre-concentration, a first in spectroscopic analysis of SP.

Funding statement

This work was funded by the National Science Foundation’s Earth Sciences Instrumentation and Facilities program (grant #1456430) and the Department of Energy Great Lakes Bioenergy Research Center (DOE BER Office of Science DE-FC02-07ER64494). The authors declare that they have no conflict of interest.
